

Torulopsis glabrata and Candida albicans in female genital infections in the Sudan*

EL-FADIL E OMER,† S A GUMAA,† H A EL-NAEEM,‡ AND M HAG ALI§

From the Department of †Medical Microbiology and ‡Obstetrics and Gynaecology, Faculty of Medicine, Khartoum, and the §Sudan Medical Research Council, Khartoum, Sudan

SUMMARY Four hundred and seventy Sudanese women with vaginal discharge were investigated for yeast-like fungi. High vaginal specimens were cultured and isolates fully identified according to standard mycological techniques. All patients were married and some were pregnant.

Of 138 yeast-like fungi identified, *Torulopsis glabrata* (34·1%) was the commonest followed by *Candida albicans* (25·4%) and *Candida krusei* (14·5%). Differing social and economic factors may be responsible for the higher prevalence of *T glabrata* in the Sudan. Although its pathogenicity is not well established, its association with vulvovaginitis should not be overlooked.

Introduction

Fungal infection of the vagina was recognised as a pathological condition in the nineteenth century.¹ In the Sudan studies have been carried out to determine the importance and incidence of mycotic infections in men² and women.^{3,4} Mycotic agents may be actual or potential pathogens in the genital tract, and many workers have studied their distribution in various population groups, often with conflicting results. Different species of the genera *Candida* and *Torulopsis* have been isolated and correlated with the pathological condition.⁵

The aim of this study was to determine the prevalence of yeasts and yeast-like fungi in the vagina of Sudanese women presenting with vaginal discharge.

Patients and methods

The patients investigated were adult women presenting with vaginal discharge to the sexually transmitted diseases clinic at Samir Health Centre, Khartoum. Some of the patients were diagnosed as having acute vaginitis and others pelvic inflammatory disease. None of the patients was diabetic or unmarried. Although some were pregnant, many were using oral contraceptives.

CULTURE TECHNIQUE

Single vaginal specimens were collected using a Cusco's bivalve speculum.⁴ Material from the vaginal wall was collected with a sterile wire loop and inoculated directly on to glucose-peptone agar (Sabouraud's medium) with 0·05% chloramphenicol and transported to the laboratory within 30 minutes. Cultures were incubated at 37°C for 24-48 hours.

IDENTIFICATION OF YEASTS

Films were made from all cultures showing growth, stained by Jensen's modification of Gram's stain, and examined for yeasts. Further identification was carried out on all the isolated yeasts by germ-tube production in human serum and chlamydospore formation on corn-meal agar. Sugar fermentation (zymogram) and sugar assimilation (auxanogram) of glucose, maltose, sucrose, lactose, galactose, trehalose, raffinose, and cellobiose were also performed, as well as nitrogen assimilation of potassium nitrate and asparagin.³

Interpretation of results was carried out according to the method of Emmons *et al.*⁶

Results

Of 470 specimens investigated, yeast-like organisms were grown from 138 (29·7%). The species of yeasts isolated are shown in the table.

CANDIDA SPECIES

Candida species (87 isolates) were the predominant organisms in all specimens investigated (18·5%) and in all cultures showing growth (63%). *Candida albicans* was the commonest species of *Candida*

TABLE Types of yeasts isolated

| Type of yeast | No isolated | % of total |
|---------------------------------------|-------------|------------|
| <i>Candida albicans</i> | 35 | 7.4 |
| <i>Candida krusei</i> | 20 | 4.3 |
| <i>Candida parapsilosis</i> | 7 | 1.5 |
| <i>Candida stellatoidea</i> | 6 | 1.3 |
| <i>Candida parakrusei</i> | 4 | 0.9 |
| <i>Candida guilliermondii</i> | 4 | 0.9 |
| <i>Candida pseudotropicalis</i> | 2 | 0.4 |
| <i>Candida tropicalis</i> | 1 | 0.2 |
| <i>Candida</i> species (unidentified) | 8 | 1.7 |
| <i>Torulopsis glabrata</i> | 47 | 10.0 |
| <i>Torulopsis candida</i> | 2 | 0.4 |
| <i>Trichosporon cutaneum</i> | 1 | 0.2 |
| <i>Rhodotorula rubra</i> | 1 | 0.2 |
| Contaminated cultures | 31 | 6.6 |
| No growth | 301 | 64.0 |
| Total No of specimens | 470 | 100.0 |

isolated followed by *C krusei*. Their isolation rates in relation to the total *Candida* species identified were 40.2% and 23% respectively.

TORULOPSIS SPECIES

Torulopsis species (49 isolates) occurred next in frequency to *Candida* species in all specimens (10.4%) and in all isolates showing growth (35.6%) *Torulopsis glabrata* was the most frequently isolated species in this genus and was isolated more often (10%) than *C albicans* (7.4%). Of the total number of yeasts isolated (138), *T glabrata* was the commonest (34.1%), then *C albicans* (25.4%) and *C krusei* (14.5%).

Discussion

Yeasts and yeast-like fungi are widely distributed in nature and in the Sudan. In a study to evaluate the importance of yeasts isolated from urine specimens of female Sudanese patients, Gumaa³ found the commonest was *C krusei* followed by *C albicans* and *T glabrata*. Omer⁴ studied species of *Candida* isolated from vaginal discharge of Sudanese women in Khartoum and reported that 29.2% harboured the organism; *C albicans* represented 20.5% of the *Candida* species isolated.

T glabrata may rarely cause vaginitis and is frequently isolated from vaginal swabs sent for the diagnosis of vaginitis.¹ It can produce a clinical and symptomatic picture similar to that of the genus *Candida*.⁵ Most of the yeast-like fungi are secondary pathogens in patients with a primary disease. *T glabrata* has a low degree of virulence, but it can sometimes cause a secondary infection.⁶

It is now widely accepted that *C albicans* is not part

of the normal flora of the vagina and that its presence indicates morbidity.¹

In England *C albicans* was found to be the commonest infectious agent isolated from female patients attending clinics for the diagnosis of sexually transmitted diseases. *C krusei*, *C stellatoidea*, and *C tropicalis* were also associated with vaginitis in some other countries.⁵ In a study carried out at Queen Charlotte's Hospital, London, *C albicans* comprised 94% of all isolates of yeasts from women with mycotic vulvovaginitis and *T glabrata* accounted for 3.5%.¹ Morton and Rashid⁷ quoted that *C albicans* is responsible for 80-95% of cases of vulvovaginitis and *T glabrata* for 3-16%. It was concluded that there is a geographical variation in the species of *Candida* producing genital candidosis. This is not unexpected in view of the importance of diet and climatic and host factors.⁵ Furthermore, social and economic factors may affect the geographical distribution of yeasts.⁶

In our study *T glabrata* was more prevalent than *C albicans* (table). This result differs from other reports and may be explained by the different environmental conditions and habits of the Sudanese people compared with those of other societies. Although the pathogenicity of *T glabrata* is not as well established as that of *C albicans*, its association with vulvovaginitis should not be overlooked. Further studies are required in similar countries to confirm these findings.

Our thanks are due to the medical officer-in-charge, Samir Health Centre, Khartoum, for his support and co-operation. The assistance of technicians in the mycology laboratory of the Faculty of Medicine, Khartoum, is gratefully acknowledged.
